

Microgrid economics south africa

Electricity minister Kgosientsho Ramokgopa recently announced that South Africans experienced 600 hours less load shedding over the past three months than they did in the same period last year. While welcome, the threat of load shedding persists, with varying levels expected over the course of 2024.

In response, a growing number of South Africans are turning to rooftop solar to mitigate the impacts. However, microgrids could emerge as an augmented solution to address the country's ongoing energy challenges.

Microgrids operate on the fundamental principle of bringing power generation to the point of consumption, providing communities with autonomy over their energy needs. They are decentralised power systems that generate and distribute electricity locally, serving specific communities or individual facilities, such as university campuses, hospital complexes, business centres or gated communities.

Microgrids can be "islanded", meaning they can be disconnected from the national grid, operating autonomously, with power typically being produced from renewable sources like rooftop solar and small-scale wind turbines.

If necessary, they can remain connected to the grid to draw power if it is required, but the primary goal is to enhance energy resilience, reduce dependence on the grid and empower communities to manage their energy resources efficiently. Microgrids, therefore, have the potential to mitigate the impact of load shedding while also enhancing energy security.

There has been some success with partial hybrid microgrid solutions, particularly in environments such as sectional title properties or gated communities through their ability to leverage roof space, generate significant power and accommodate large-scale batteries. The next step will be to make these systems completely independent, whereafter the concept could be expanded to larger areas, such as blocks within a neighbourhood.

In smaller, close-knit communities, the integration of microgrid systems connected to the main distribution transformer rooms is already being explored. These community-driven microgrids foster collaboration, allowing residents to share, sell and optimise their renewable energy resources.

As such, microgrids have the potential to help alleviate the impact of load shedding in South Africa. By creating microgrids within residential and commercial areas, we can form "islands" that connect to the main grid but are also capable of independent power generation and sharing.

This enhances community self-sufficiency. It also allows for bulk resale of power back into the grid, which

streamlines interactions with Eskom, rather than many individuals trying to sell power back to the utility.

This is best achieved through a unified community body that negotiates effectively. For instance, proposing a collective contribution of 50kW per community could have a significant impact when multiplied across numerous communities, offering a scalable model that contributes substantially to the overall energy needs of the country.

A model involving the integration of microgrids with existing infrastructure, such as municipalities, makes sense. This collaborative approach allows communities to maintain and upgrade their microgrid infrastructure, creating employment opportunities and a self-sustaining system. Whether through a contract fee or a monthly stipend, the community could hold appointed individuals accountable for upkeep.

The model also suggests collaboration with utility providers for a higher-level supply agreement. Keeping them in the loop or negotiating as a community could lead to a self-funding model, gradually allowing communities to be self-sustaining. This approach has the potential to revolutionise power infrastructure for community independence and stability, along with greater resilience of the national supply.
